ABSTRACT

Satellite based retrievals of evapotranspiration (ET) are widely used for assessments of global and regional scale surface fluxes. However, the partitioning of the estimated ET between soil evaporation, transpiration, and canopy interception regularly shows strong divergence between models, and to date, remains largely unvalidated. To examine this problem, this paper considers three algorithms: the Penman-Monteith model from the Moderate Resolution Imaging Spectroradiometer (PM-MODIS), the Priestley-Taylor Jet Propulsion Laboratory model (PT-JPL), and the Global Land Evaporation Amsterdam Model (GLEAM). Surface flux estimates from these three models, obtained via the WACMOS-ET initiative, are compared against a comprehensive collection of field methods, and predictions also in precipitation regimes. Modeled estimates of soil evaporation were found to have significant deviations from observed values across all three models, while the characterization of vegetation effects also influences errors in all three components. Improvements in these estimates, and other satellite based partitioning estimates are likely to lead to better understanding of the movement of water through the soil-plant-water continuum.

1. Introduction

The evaporation of water from the Earth’s surface to the atmosphere represents a critical link between the global water, carbon, and energy cycles (Oki and Kanae, 2006). An estimated two thirds of terrestrial represent a critical link between the global water, carbon, and energy cycles (Oki and Kanae, 2006). An estimated two thirds of terrestrial processes. Hence, the partitioning of the estimated ET between soil evaporation, transpiration, and canopy interception regularly shows strong divergence between models, and to date, remains largely unvalidated. To examine this problem, this paper considers three algorithms: the Penman-Monteith model from the Moderate Resolution Imaging Spectroradiometer (PM-MODIS), the Priestley-Taylor Jet Propulsion Laboratory model (PT-JPL), and the Global Land Evaporation Amsterdam Model (GLEAM). Surface flux estimates from these three models, obtained via the WACMOS-ET initiative, are compared against a comprehensive collection of field methods, and precipitation regimes. Modeled estimates of soil evaporation were found to have significant deviations from observed values across all three models, while the characterization of vegetation effects also influences errors in all three components. Improvements in these estimates, and other satellite based partitioning estimates are likely to lead to better understanding of the movement of water through the soil-plant-water continuum.

Climate warming is expected to significantly alter the global water cycle, affecting regional and global rates of ET, precipitation, and streamflow (Huntington, 2006; Zhang et al., 2016). Given the important role of ET in a variety of land surface processes, accurately estimating large-scale fluxes of ET is critical to our understanding of the earth system. Spatially distributed, remote sensing-based ET models have become a dominant means to estimate catchment and global-scale ET fluxes (Anderson et al., 2007; Fisher et al., 2017; Schmugge et al., 2002). The large spatial extent and fine temporal resolution of these remote sensing products makes them perhaps the only observational means to assess global-scale impacts of changes in ET fluxes. These factors have made remote sensing-based models a powerful tool in both climate and large-scale hydrologic applications. Many of these remote sensing-based models estimate total ET via combination of its separate components: transpiration through plant stomata, soil evaporation from the top layer
of soil, and canopy rainfall interception. However, the wide array of algorithms and choice of forcing datasets have hampered the analysis of model results, as errors in model estimates may come from both forcing errors and/or errors in algorithms and parameterizations (Ershadi et al., 2015). Recent efforts have compared ET fluxes from several satellite-based ET models using a common forcing dataset, simplifying the comparison substantially (McCabe et al., 2016; Michel et al., 2016; Miralles et al., 2016).

These remote sensing-based ET estimates have shown good relative agreement in global estimates, but larger discrepancies regionally (Michel et al., 2016). Interestingly, the limited number of studies comparing individual ET components have shown that the global and regional contribution of transpiration, soil evaporation, and interception vary significantly between models, even where total ET estimates agree (Miralles et al., 2016). The divergence of ET partitioning estimates suggests that some models may contain large ET partitioning errors. Accurate partitioning estimates are highly desired for research related to agriculture, climate and land-use change, hydrology, and water resource availability. ET partitioning is also a crucial factor for global climate models as the partitioning of ET has proven to be a significant source of uncertainty for future climate projections (Lawrence et al., 2007). Incorrect parameterizations within ET models are likely to compromise the accuracy of estimates across ecoregions and through time. Furthermore, any divergence of ET partitioning is certainly an indicator that models may contain systematic errors in their formulations.

The mechanisms that govern the individual ET components of transpiration, soil evaporation, and canopy interception operate on varying spatial scales from relatively small (i.e. stomata, single plants) to larger regional scales (i.e. climate system) (Good et al., 2017; Pieruschka et al., 2015; Wang and Dickinson, 2012; Wang et al., 2014). Field methods for measuring transpiration typically measure at the scale of an individual leaf or plant (Bana and Katerji, 2000; Schlesinger and Jasechko, 2014). Such field techniques include: sap-flow measurements, diurnal water table changes, water-balance approaches, and isotope based approaches (Gibson and Edwards, 2002; Lautz, 2008; McJannet et al., 2007; Nizinski et al., 2011). Measurements from such studies are extrapolated to larger spatial scales through assumptions about the variability of sap-flow densities (Dye et al., 1991; Fernández et al., 2006), changes in isotopic composition of water within the plant (Brunel et al., 1997), and general homogeneity of vegetation and stomatal response to environmental conditions. The spatial scale of these measurements remains a limitation for ET partitioning validation, as research into regional hydrologic and climatic processes often requires estimates of partitioned fluxes at much larger spatial scales.

Furthermore, field studies of ET partitioning often focus on a single component such as transpiration or interception, and rarely attempt to estimate all contributing ET components. Canopy interception, for instance, is a well-developed field of study (Carlyle-Moses and Gash, 2011; Croxford and Richardson, 2000; Levia and Frost, 2006; Muzio et al., 2009), and is often assessed as the difference between rainfall above and below the canopy. However, few canopy interception studies attempt to quantify the role of interception as part of the ET flux. Similarly, transpiration studies are often focused on the physiologic processes of vegetation and disregard the role of transpiration in larger hydrologic and atmospheric cycles. Some field methods do not directly measure soil evaporation, and instead quantify it as the residual of ET and transpiration. Due to the fractured nature of the ET partitioning research, few field studies are available quantifying transpiration, soil evaporation, and interception simultaneously.

To address the uncertainty surrounding ET partitioning in remote sensing-based ET models, we evaluate three models and their partitioning strategies against a compilation of field studies. We hope to contextualize partitioning comparisons made by Miralles et al. (2016) using empirical field methods. While previous studies have attempted to compare specific model estimates of either canopy interception or transpiration against field data, few have jointly assessed errors in remote sensing-based estimates against transpiration, soil evaporation, and interception. In comparing model performance against compiled field estimates we hope to (1) reconcile the deviations between each model partition against a field standard, (2) determine if the modeled errors are consistent or vary across different land surface or climate conditions, (3) identify assumptions or parameters within the model that contribute to error, and (4) contextualize some of the partitioning comparisons made by Miralles et al. (2016).

2. Methodology

We compared ET components from three remote sensing-based models against a compilation of field estimates of soil evaporation, transpiration, and interception. We assessed the Priestley-Taylor Jet Propulsion Lab model (PT-JPL)(Fisher et al., 2008), the Penman-Montheith MODerate Resolution Imaging Spectroradiometer (PM-MODIS) (Mu et al., 2011), and the Global Land Evaporation Amsterdam Model (GLEAM) (Martens et al., 2017; Miralles et al., 2011, 2010) model. Each model is widely used to estimate ET and provide relatively comparable estimates of the total ET flux (Miralles et al., 2016). Global annual mean values of ET for each model have been estimated at 54.9, 72.9, and 72.5 × 10^6 km^2 for PM-MODIS, GLEAM, and PT-JPL respectively (Miralles et al., 2016).

2.1. Evaporation models

Each model evaluated for this study adopts a similar structure to estimate total ET fluxes as well as the individual components of ET. The model structure may be categorized into three separate functions: (1) quantifying potential ET, (2) partitioning the potential ET into its given components to be aggregated as total ET, and (3) translating the potential ET into an actual ET based on the constraints of the component processes. Different models employ different strategies in accomplishing these basic functions but individual model parameters often fall into a single categorical function.

2.1.1. Priestley-Taylor Jet Propulsion Lab (PT-JPL)

The PT-JPL model utilizes the Priestley-Taylor equation (Priestley and Taylor, 1972) to estimate potential ET flux and is described in depth in Fisher et al. (2008). The model uses ecophysiological and atmospheric constraints to reduce the potential ET flux to an actual ET flux. The total ET is partitioned between soil evaporation, E_s [m/s], canopy transpiration, E_t [m/s], and canopy interception, E_i [m/s] as

\[ E_i = (1 - f_SM) \Delta \frac{\lambda_i \rho_v \Delta}{\lambda_i \rho_v \Delta + \rho_v G} \] (1a)

\[ E_s = f_SM \frac{\lambda_i \rho_v \Delta}{\lambda_i \rho_v \Delta + \rho_v G} R_{ac} \] (1b)

\[ E_t = f_SM \frac{\Delta}{\lambda_i \rho_v \Delta + \rho_v G} R_{ac} \] (1c)

where \( \Delta \) is the Priestley-Taylor coefficient (considered equal to 1.26), \( G \) is the slope of the vapor pressure curve [Pa/K], \( k \) is the psychrometric constant [Pa/K], \( R_{ac} \) is the net radiation [W/m^2], \( G \) is the energy flux into the ground [W/m^2], \( \lambda \) is the latent heat of vaporization[J/kg], \( f_SM \) is a relative surface wetness parameter (see below), \( f_SM \) is the soil moisture constraint, \( f_t \) is the green canopy fraction, \( f_j \) is the plant temperature constraint, and \( f_M \) is the plant moisture constraint.

PT-JPL effectively accomplishes its partitioning using a canopy extinction equation to estimate the radiation penetrating through the canopy. This canopy extinction equation utilizes the leaf area index (LAI) in conjunction with the Beer-Lambert law of light attenuation (Norman Ay et al., 1995) to partition net radiation between the canopy and soil. Canopy processes (interception and transpiration) are
determined using the radiation intercepted according to the Beer-Lambert equation, and soil evaporation is determined using the residual radiation penetrating the canopy.

PT-JPL scales each ET component by various scalars \( f \) parameters between 0 and 1 to account for environmental constraints on potential evaporation such as water and heat stress. Transpiration is constrained using four vegetation-based physiological parameters. Temperature and plant moisture effects on transpiration are calculated by normalizing phenological parameters by the maximum observed value per pixel. A canopy greennis fraction further constrains the transpiration flux based on the ratio between the fraction of absorbed photosynthetically active radiation (\( f\text{APAR} \)) and the fraction of intercepted photosynthetically active radiation (\( f\text{PAR} \)). The fourth constraint on transpiration is the surface wetness based on atmospheric relative humidity (\( f_{\text{sw}} \)). Soil evaporation constraints are determined by the surface wetness parameter (\( f_{\text{sw}} \)) and the available soil moisture (\( f_{\text{sm}} \)), the latter estimated by both relative humidity and vapor pressure deficit. Interception is estimated using the same \( f_{\text{sw}} \) parameter.

2.1.2. Penman-Monteith MODerate Resolution Imaging Spectroradiometer (PM-MODIS)

The PM-MOD model uses a framework based on the Penman-Monteith equation and utilizes specific conductance terms representing the vapor movement from the land surface to the overlying atmosphere. The model is described in depth by Mu et al. (2011) and estimates the components as:

\[
E_i = f_{\text{sw}} E_i^\text{PM} = \frac{\Delta (R_n - G) + \rho c_p f_{\text{APAR}}}{\lambda_i \rho_a (\Delta + \gamma_{\text{at}})} \tag{2a}
\]

\[
E_i = (1 - f_{\text{sw}}) E_i^\text{PM} = \frac{\Delta (R_n - G) + \rho c_p f_{\text{PAR}}}{\lambda_i \rho_a (\Delta + \gamma_{\text{at}})} \tag{2b}
\]

\[
E_i = f_{\text{sw}} + (1 - f_{\text{sw}}) h \equiv f_{\text{sw}} \frac{\rho c_p (1 - f_{\text{APAR}})}{\lambda_i \rho_a (\Delta + \gamma_{\text{at}})} (s \times \Delta \text{soil} + \rho c_p (1 - f_{\text{APAR}})) \tag{2c}
\]

Interception, transpiration, and soil evaporation are separated using fractional cover, \( f_{\text{c}} \), calculated using \( f\text{APAR} \). The partitioned fluxes are constrained based on relative humidity (\( h \)), the fraction of wet surface (\( f_{\text{sw}} \)), and look-up table values of vegetation-dependent aerodynamic and surface resistances (\( \tau_i, r_i \)).

2.1.3. Global Land Evaporation Amsterdam Model (GLEAM)

Similarly to PT-JPL, GLEAM relies on a Priestley-Taylor framework to calculate potential ET. GLEAM uses a separate algorithm to calculate interception (\( E_i \)) based on a Gash analytical model (Gash, 1979; Valente et al., 1997) driven by precipitation observations. \( E_i \) estimates have been previously validated against field data independently (Miralles et al., 2010). The GLEAM model computes interception only for the tall canopy fraction within each pixel (see below).

Then soil evaporation (\( E_s \)), tall canopy transpiration (\( E_{tc} \)) and short canopy transpiration (\( E_{sc} \)) are calculated as

\[
E_i = f_s S_i \alpha_i \Delta (R_n - G) \tag{3a}
\]

\[
E_{tc} = f_t S_t \alpha_t \Delta (R_n - G) \tag{3b}
\]

\[
E_{sc} = f_s S_c \alpha_c \Delta (R_n - G) \tag{3c}
\]

The transpiration (\( E_t \)) is then calculated as the sum of \( E_{tc} \) and \( E_{sc} \). In Eqs. (3a)–(3c), the partitioning of the evaporative flux into different components is based on the fractional vegetation cover (\( f \)). The fractional cover utilized is the MODIS Continuous Vegetation Fields product, MOD44B, which describes each pixel as a combination of bare soil, tall canopy, and short canopy vegetation (i.e. “s”, “c”, and “sc”, respectively). The model uses vegetation-dependent parameterizations of \( \alpha \) as well as different values of \( a \) for each vegetation cover type. Characteristic albedo ratios per vegetation cover type come from look up tables and determine how \( R_n \) is distributed per cover fraction.

GLEAM model constrains the Priestley and Taylor potential evaporation estimates based on an evaporative stress factor. This stress factors, \( S \), is parameterized separately for the bare soil, tall canopy, and short vegetation components based on soil moisture and vegetation phenology for the vegetated fractions (see \( S_s, S_t \) and \( S_c \) in Eqs. (3a)–(3c), respectively). The soil moisture is estimated based on a multilayer soil module driven by precipitation observations, and further optimized using a data assimilation system that incorporates observations of surface soil moisture (Martens et al., 2017, 2016). The transpiration stress associated with phenological changes is based on microwave vegetation optical depth, a proxy for vegetation water content (Miralles et al., 2011).

2.2. Field validation data

Field studies measuring the separate components of ET (i.e. soil evaporation, transpiration, and interception) are scarce. We utilized a set of studies previously consolidated by Schlesinger and Jasechko (2014) as well as additional studies containing annual values for transpiration and total ET. We then calculated soil evaporation as the residual of transpiration and total ET, assuming negligible interception. We compared the residual field estimate against modeled soil evaporation and the modeled residual (ET-T) and found that this assumption did not significantly influence the aggregate results of the study. These studies span several decades and use a variety of measurement techniques, primarily sap-flow measurements, isotope-based measurements, or meteorological models scaled using eddy-covariance and water balance models. Other studies have scaled measurements using biophysical models or through a water balance method to obtain canopy level values of transpiration and ET. Each field method suffers from their own set of assumptions and is associated with some measurement error. Field study site locations are displayed in Fig. 1 and listed in Table 1. Despite the range of spatial support and uncertainty related to each technique in the dataset, we believe that, in the aggregate, the field estimates offer a good means to evaluate the performance of the model estimates.

Some field studies within the dataset span only the growing season of a given year and may overestimate the ratio of transpiration to ET on an annual scale. Other studies span several years and report a single annual estimate for transpiration and ET fluxes. Field estimates are reported as annual values and are compared against the modeled annual means. Instances exists where separate field studies reported values for the same pixel, in which case the field estimates were averaged.

The field studies described above largely ignore evaporation of rainfall intercepted by the canopy. To validate the interception components of the models we used the dataset previously used in the validation of the GLEAM interception loss estimates (Miralles et al., 2010). This dataset includes studies estimating the interception of forested canopies and excludes field sites in grasslands or shrublands where herbaceous interception may occur. The field dataset describes the interception at a given site as a mean annual depth per area of canopy. In order to estimate the interception in a given pixel, we scaled each field value using the fraction of forested land cover described by the MCD12C1 land cover fraction product [dataset] (NASA LP DAAC, Friedl and Sulla-Menashe, 2015). This does not account for the interception by herbaceous vegetation in non-forested areas, even though the rates of interception by short vegetation are expected to be comparatively much lower due to differences in aerodynamic conductance (David et al., 2005).
2.3. Model forcing data

For the WAter Cycle Observation Multi-mission Strategy - ET forcing database (WACMOS-ET, http://wacmos.etstellus.eu/), which includes remote sensing derived surface meteorology and radiation fluxes (Michel et al., 2016; Miralles et al., 2016). In addition to the parameters already included in the WACMOS-ET forcing dataset, the PM-MOD model requires LAI, IGBP land cover, and fAPAR as inputs while the PT-JPL model requires NDVI. The original WACMOS-ET dataset contains LAI and fAPAR derived from the Joint Research Centre two-stream inversion package, but the values are not consistent with the MODIS derived derived LAI and fAPAR that both PM-MOD and PT-JPL require. We used MODIS vegetation products [dataset] (NASA LP DAAC, Didan, 2015) to supplement the WACMOS-ET data to force the PT-JPL and PM-MOD.

The input datasets vary in spatial and temporal resolution, but are re-sampled to a common 0.25° latitude × 0.25° longitude grid, and a 3-hourly temporal scale for PT-JPL and PM-MOD models, and a daily temporal scale for GLEAM. GLEAM no longer provides sub-daily estimates of ET, but PT-JPL requires maximum daily temperature and minimum daily humidity and is thus executed using the original 3-hourly forcing. In addition to the time variant fields, both GLEAM and PM-MOD require static fields. PM-MOD requires IGBP land cover values while GLEAM requires soil parameters derived from IGBP-DIS (Global Soil Data Task, 2014), and the MOD44B global vegetation continuous fields product.

3. Results & analysis

We compared the modeled estimates for each ET component against the field study estimates at each location. Table 2 lists the $r^2$ correlation coefficient, the standard error, the percent mean bias deviation (%MBD), and the percent root mean squared deviation (%RMSD) across different models. Fig. 2 shows linear regressions of the modeled estimates against the field estimates for each model and individual ET component.

Total ET results are comparable between models and show similar agreement with previous validations of total ET (Miralles et al., 2016). The modeled estimates generally overestimate the field estimates for small ET fluxes, and underestimate the field estimates at high values. Both PM-MOD and GLEAM show a tendency to underestimate the total flux, exhibiting a percent mean bias deviation (%MBD) of $-21.6\%$ and $-20.9\%$ respectively. PT-JPL ET estimates shows a %MBD of just $-2.3\%$. The standard error exhibited by each model is very similar as are the overall trends. Comparatively, the modeled partitions show large discrepancies among themselves and against field data.

GLEAM offers the best results for estimating the transpiration flux, showing the lowest %RMSD, %MBD, and highest $r^2$ value. PT-JPL shows similar results to GLEAM for most statistics, except a lower correlation. The %MBD for the PM-MOD transpiration flux is $-66.0\%$, which is substantially larger as compared to PT-JPL and GLEAM, where values of $-10.7\%$ and $-5.4\%$ are obtained respectively. The PT-JPL transpiration correlation ($r^2 = 0.33$) is much lower than previous validations of the transpiration component by Fisher et al. (2008) using sap flow estimates at three flux tower sites of alpine and sub-alpine climates. Compared to these three flux tower sites, our partitioning data spans a greater range of climate at a coarser temporal resolution. Recall that the slight underestimate of PT-JPL and GLEAM transpiration could be the result of certain model deficiencies.

Both GLEAM ($r^2 = 0.82$) and PM-MOD ($r^2 = 0.85$) offer high correlations with field interception estimates. However, GLEAM shows lower RMSD (62.1%) and MBD (25.3%) as compared to PM-MOD (181.0% RMSD, 149.9% MBD). PT-JPL estimates of canopy interception compare poorly based on all statistical measures, resulting in an $r^2$ correlation of only 0.39 and a RMSD of 157.4%. Overall, estimates of interception showed a large level of divergence with the field estimates for both PM-MOD and PT-JPL. Model estimates showed especially large errors where field estimates exhibited small fluxes or where the fraction of forest within the pixel was determined to be small. However, the small number of field interception studies (N = 13) makes it difficult to definitively assess the model performance.

While the PT-JPL model provided the highest $r^2$ value and lowest RMSD for soil evaporation (89.8%RMSD, $r^2 = 0.25$), the results are relatively poor compared to the transpiration estimates. Modeled estimates of soil evaporation were inaccurate across all models and displayed little agreement with the field estimates. GLEAM, while exhibiting a low standard error (0.05), consistently underestimated the flux of soil evaporation compared to the field results ($-45.6\%$MBD), which is mostly responsible for the bias in total ET exhibited by GLEAM. Conversely, PT-JPL estimates showed little bias (11.0%MBD) and a relatively high standard error (0.17). PM-MOD performed poorly across all statistical measures, exhibiting a positive bias (49.4%MBD).

Grouping the results by land cover type, water availability, and observational method allows us to identify how model performance changes across these groups. Fig. 3 shows the relative error for each model estimate against field estimates categorized by land cover type. We consolidated IGBP land cover values into four new groupings: forests (IGBP #1-5), shrublands (IGBP #6-7), grasslands (IGBP #8-10), and cropland and urban (IGBP # 0, 11-16). An analysis of each IGBP classification individually was impractical given the small number of values in each land cover group.

GLEAM, when analyzed across land cover, generally shows more variance in shrublands and grasslands and comparatively little variance in forests. This is most evident in the GLEAM model estimates of soil

</table>
evaporation, where the modeled estimates are extremely consistent in forests, less so in grasslands and croplands, and least in shrublands. As the GLEAM soil evaporation estimates become less consistent across these land cover types, the bias of these estimates shifts positively. A strong negative bias is evident in forests, and a positive one develops in shrublands. Similarly, the GLEAM model shows higher variance in its estimate errors of transpiration in shrublands and grasslands, and smaller variance in forests.

The differences between land cover types when considering interception become difficult to interpret because of the small amount of data in non-forested areas. The field interception dataset reports values exclusively from forests, so a non-forested land cover type for that location may suggest that the study site is not representative of the larger pixel. Apart from interception, PT-JPL and PM-MOD show little change in the bias of their estimates depending on land cover. Generally, all three models show a wider variation in estimate error in shrublands and grasslands than in forests.

Fig. 4 shows the relative estimate error of each model across different precipitation regimes. Each model shows large errors in interception at low precipitation, with PM-MOD exhibiting large sensitivity to annual precipitation. The relative error of the GLEAM soil evaporation trends negatively with increasing precipitation as does the PT-JPL estimate of total ET.

Fig. 5 shows the relative error of each model plotted by the field method used to partition ET. Estimates in soil evaporation are constant across field method, as are estimates in total ET to a lesser extent. Recall that soil evaporation is calculated as the residual of ET and transpiration, so that error in the observational method will be reflected in both transpiration and soil evaporation components. The PM-MOD transpiration estimates are also consistent, showing a clear negative bias regardless of field method. However, GLEAM and PT-JPL estimates vary slightly, while showing consistent estimates to one another.

4. Discussion
One of the inherent limitations in remote sensing-based evaluation studies is the challenge of acquiring independent observations that are representative of the scale of measurement. As such, we acknowledge that the spatial and temporal scale of the field-based estimates used in this study are not the ideal dataset for assessing the performance of these models, but few alternatives exist to estimate the individual components of ET. While eddy covariance observations are much better equipped for comparison with larger spatial fluxes and the finer temporal resolution of remote sensing-based ET products, they do not offer information regarding the individual components of ET. The field studies used in our analysis use a wide range of scaling techniques to acquire a canopy level ET measurement, and include eddy flux towers. Inevitably, some approaches are likely to be smaller in spatial scale than the satellite estimates, but, in the aggregate, still offer insight into how ET should be partitioned.

Our results show a moderate variation in total ET between each of the models, in agreement with previous studies (Michel et al., 2016; Miralles et al., 2016). However, the objective of this study is primarily the evaluation of the evaporation partitioning in these models. As large discrepancies exist between the separate fluxes estimated by different models, they are likely to overshadow the measurement error between field methods.

Clear patterns between modeled estimates are evident in the soil evaporation components of each model as well as the PM-MOD component of transpiration. This is illustrated in Fig. 5, where differences in modeled estimates are consistent regardless of the field method employed. PT-JPL and GLEAM estimates of transpiration show similar results, while varying slightly across different field methods. This highlights the difficulties in disentangling the results of PT-JPL and GLEAM transpiration, given the errors that may exist in the field data. As such, we will only discuss where clear differences between models exist or where the models show large biases with respect to the field data.

Through rooting uptake, plants are able to utilize water for transpiration held in the soil long after rain events. Soil evaporation and interception are much more dependent on transient rain events, which increase water storage in the canopy or upper layer of soil that becomes available for fast evaporation (Williams et al., 2004; Yepez et al., 2005). The available water source for either flux also depends on the connectivity of that water to surface water or deeper soil stores (Good et al., 2015). The differences in water sources for separate evaporation components changes the fundamental nature of those processes and the modeling techniques and data required to capture these physical processes. While fine temporal sampling may be required to capture rain events contributing to soil evaporation and interception, it may not be required to capture transpiration rates.

The modeled soil evaporation shows little correlation with field estimates across all models. In addition, both PT-JPL and PM-MOD show large standard error in their estimates of soil evaporation. While the inability of model routines to fully capture the physical process of soil evaporation might be responsible for part of the total error, differences in the spatial and temporal scales of soil evaporation as compared to transpiration may contribute to larger standard error in the results of soil evaporation. Soil moisture dynamics have shown to vary significantly in time and space depending on the antecedent conditions (Grayson et al., 1997). Moreover, changes in the lateral or vertical movement of water in soil associated with these changes could affect the connectivity to surface water flows and the availability of water for soil evaporation. Soil evaporation, being highly dependent on spatially variable soil moisture, could thus be disproportionately influenced by the differences in spatial scale between the field and modeled estimates. Additionally, different model representations of ground heat flux directly contribute to uncertainties in soil evaporation (Purdy et al., 2016).
Estimates of soil evaporation from GLEAM clearly underestimate the field measurements. The relative error in soil evaporation estimates is highly correlated with the MOD44B products, showing a tendency to underestimate field measurements corresponding with areas of higher fraction of vegetation and lower bare soil. This arises due to the fact that GLEAM only considers soil evaporation from bare soil and does not estimate the soil evaporation occurring under the canopy or under herbaceous vegetation. The higher correlation of the estimate error with herbaceous vegetation than tall canopy suggests that the underestimation of soil evaporation by GLEAM is more significant in areas of herbaceous vegetation. Figs. 3 and 4 further corroborate this result.

Estimates of soil evaporation from GLEAM clearly underestimate the field measurements. The relative error in soil evaporation estimates is highly correlated with the MOD44B products, showing a tendency to underestimate field measurements corresponding with areas of higher fraction of vegetation and lower bare soil. This arises due to the fact that GLEAM only considers soil evaporation from bare soil and does not estimate the soil evaporation occurring under the canopy or under herbaceous vegetation. The higher correlation of the estimate error with herbaceous vegetation than tall canopy suggests that the underestimation of soil evaporation by GLEAM is more significant in areas of herbaceous vegetation. Figs. 3 and 4 further corroborate this result. The underestimation in soil evaporation is most apparent in forested land cover and shows a negative relationship with increasing rainfall. As shown in Fig. 2, this causes most of the underestimation in the GLEAM estimates of total ET.

PM-MOD and PT-JPL share their approach to scale the soil evaporation using observations of relative humidity and vapor pressure deficit. As a result, they largely show similar estimates of soil evaporation, and similar validation statistics. Therefore, different parameters must cause the divergences found in the soil evaporation products of PT-JPL and PM-MOD. Differences in the Penman-Monteith and Priestley-Taylor models often depend on the parameterization of $\alpha$ in the Priestley-Taylor equation and resistance factors in the Penman-Monteith equation. The largest deviations between Penman-Monteith and Priestley-Taylor ET estimation occur when aerodynamic resistances and net radiation are small and VPD is high (Komatsu, 2005). Given the similarities between the model routines and output, it seems that the poor performance of the soil evaporation component likely stems from their shared assumptions.

PT-JPL and PM-MOD, by excluding precipitation and using relative humidity as a metric of a system’s overall moisture, may see significant errors when soil and air moisture are in a state of disequilibrium. VPD and RH are correlated with soil moisture over weekly to seasonal time scales, but become decoupled over shorter time periods (Novick et al., 2016). Soil evaporation, more so than transpiration, may occur over shorter time periods following precipitation events. The use of humidity-based functions to account for water availability could explain the large standard error of the PM-MOD and PT-JPL soil evaporation component. However, spatial differences in the field and remote sensing-based products could also be culpable for the error. Higher frequency observations of ET partitioning are needed to better understand short-term dynamic changes in partitioning and how to reflect these dynamics within models.

Furthermore, soil moisture has been found to have a non-linear relationship with soil evaporation that can be characterized in two stages. The first stage is characterized by capillary transport, which
Fig. 3. Relative error between modeled and field estimates based on IGBP land cover type classification from MODIS using the WACMOS-ET dataset. The original IGBP land cover types were consolidated into four groups: Forests (IGBP 1–5), Shrublands (6–7), Grasslands (8–10), and Cropland and Urban (0, 10–16).

Fig. 4. Relative error between modeled and field estimates separated into different precipitation regimes using the WACMOS-ET dataset.
sustains moisture at the soil surface. During the second stage, drying disrupts the hydraulic pathways within the soil and the vaporization plane moves below the soil surface, resulting in a significant reduction in soil evaporation (Haghighi and Or, 2013; Or et al., 2013). The point at which drying soils shift between stages of evaporation is largely dependent on physical soil characteristics and pore size and can cause dynamic shifts at hourly time scales in evaporation resistances (Aminzadeh and Or, 2017; Decker et al., 2017; Merlin et al., 2016). Neither PT-JPL nor PM-MOD consider soil properties in their estimate of soil evaporation, while GLEAM uses field capacity and wilting point to determine stress factors. The non-consideration of soil properties could be contributing to the large standard error in those soil evaporation estimates.

The transpiration estimates of both PT-JPL and GLEAM show better agreement with field estimates than their respective soil evaporation estimates. Partitioning research has shown transpiration to be the dominate flux of total ET (Jasechko et al., 2013). Therefore, the transpiration estimate of the model is critical in the models’ ability to estimate total ET. Transpiration estimation and vegetation modeling represent research areas where remote sensing provides tremendous utility. The large degree of variability in plant species and size make ground measurements of canopy scale interaction difficult. The use of vegetation indices derived from remotely sensed products are much more advantageous for measuring heterogeneous vegetation and biophysical processes such as transpiration (Glenn et al., 2008).

PM-MOD strongly underestimates the transpiration flux estimated by field techniques. The only vegetation parameter used by PM-MOD is the fraction of absorbed photosynthetically active radiation, fAPAR, along with surface and aerodynamic resistances from the literature based on IGBP land cover type. These resistances can be very difficult to parameterize, and look-up table values do not reflect the temporal variability in these resistances. However, since the underestimation is consistent across all land cover types, it seems more likely that the use of fAPAR to partition radiation, the accuracy of the model may vary seasonally as phenology changes.

GLEAM performed very well at capturing the field interception estimates, as shown in previous studies (Miralles et al., 2010). Interception has been studied extensively, but little information exists on interception rates outside of densely forested ecosystems. While GLEAM models interception only for the tall canopy fraction of the pixel, the other models estimate interception outside of forests based on leaf area index and fAPAR. Interception losses outside of forests are likely small relative to total ET fluxes (David et al., 2005), but the value of including this interception remains unknown, given that few field measurements exist outside of forests.

Comparisons of interception estimates across Amazonia conducted by Miralles et al. (2016) found that PT-JPL and PM-MOD estimates (based on the WACMOS-ET vegetation properties as input) nearly doubled the interception rates of GLEAM and field-measured values found in the literature. Furthermore, interception has been shown to correlate strongly with both rainfall intensity and volume as they relate to canopy storage capacity (Pyper et al., 2005). PM-MOD and PT-JPL lack a canopy storage parameter, instead electing to use humidity as a proxy for surface wetness, and do not use precipitation as a forcing parameter. By not defining a storage capacity for the vegetation in PM-MOD and PT-JPL, the models could overestimate the flux for rain events exceeding the canopy storage. While PM-MOD and PT-JPL rely heavily on radiation as main driver of interception, field studies have shown that the flux of interception loss is partly decoupled from the available energy (Holwerda et al., 2011). In that sense, GLEAM likely provides better remote sensing-based estimates of interception, as it builds upon the knowledge gained in ground-based research on interception, which identifies vegetation characteristics and rainfall properties as the main determinants of the flux (Gash, 1979).

5. Conclusions

While this study attempted to validate the individual components of ET, little reliable data for these individual fluxes exists. Given the paucity of field datasets, it is difficult to draw definite conclusions on the sources of error within the modeled estimates of partitioned ET fluxes. While estimates diverge significantly between models, and modeled error is likely driving the bulk of the discrepancy with field partition estimates, the field methods themselves are also prone to errors. Furthermore, it is difficult to assess if the modeled estimates deviate due to the differences in model structure, or because of different forcing datasets and errors inherent in the forcing data. Given the multiple sources of potential error, it was challenging to determine to what magnitude we could attribute partitioning error to model
methodology.

Remote sensing-based models will continue to play a dominant role in future ET research and its global implications (Fisher et al., 2017; Zhang et al., 2017). Improved spatial resolution and spectral availability of remote sensing products will undoubtedly provide a glut of modeled ET data for future researchers (Marshall et al., 2016; McCabe et al., 2017; Sun et al., 2017). However, the relative dearth of reliable field estimates for transpiration, soil evaporation, and interception inhibits quantifying the accuracy and applications of remote sensing-based ET estimates. Clearly, observations of the individual ET components are necessary to constrain ET models and improve ET accuracy for future research into climate and hydrologic dynamics. The consolidation of a global dataset of sap flux measurements (Poyatos et al., 2016) will undoubtedly present tremendous utility in validating remote sensing-based models and contribute to the advancement of ET science.

The results of this study present the first steps towards the validation of ET partitioning within remote sensing-based models. Our analysis shows that remote sensing-based ET models, despite showing similar and quite accurate total ET retrievals, produce estimates of individual components that deviate significantly from field measurements. Even for locations where the total ET is accurately modeled, the modeled components show significant deviations from observations. The uncertainty of the ET partitioning may cause model estimates to deteriorate when applied more broadly across space and time.

In particular, we find that:

- PM-MOD showed a strong negative bias in its transpiration estimate that caused a negative bias in the total ET estimate. The bias is likely related to the scaling parameters of the canopy, as PM-MOD relates the absorbed PAR linearly to the transpiration rate.
- Model estimates of soil evaporation showed little correlation with field estimates across all models. GLEAM exhibited a strong negative bias likely due to the non-consideration of below-canopy soil evaporation. Both PM-MOD and PT-JPL also exhibited large standard error in their estimates of soil evaporation.
- The quality of the interception estimates outside of forests was not assessed. GLEAM showed good agreement with the field data over forests, while PT-JPL and PM-MOD showed larger divergences. The non-consideration of rainfall and canopy storage capacity in PT-JPL and PM-MOD, and the direct dependency of interception loss on radiation, are the most likely causes for the disagreement with the field data.
- Finally, our results confirm that caution should be taken when applying any of these models in isolation, as long as the goal of the study relies heavily on the models partitioning of ET fluxes.

Data availability

The field observations and remote sensing datasets used in this study are all derived from previously published work.

The MCD12C1 data product was retrieved from the online Data Pool, courtesy of the NASA Land Processes Distributed Active Archive Center (LP DAAC), USGS/Earth Resources Observation and Science (EROS) Center, Sioux Falls, South Dakota, https://lpdaac.usgs.gov/data_access/data_pool.

The MODIS A2 data product was retrieved from the AppEARS data page, courtesy of the NASA Earth Observing System Data and Information System (EOSDIS) and the Land Processing Distributed Active Archive Center (LP DAAC), USGS/Earth Resources Observation and Science (EROS) Center, Sioux Falls, South Dakota, https://lpdaacsvc.cr.usgs.gov/appears.
